Introduction to Classification

Definition 1 (Classification)

Classification aims to learn a function that takes attribute values and predicts a categorical/qualitative value, such as membership of a class, existence of an effect, etc. The attributes can be categorical or numeric. As with linear regression, classification is an example of supervised learning. It differs from regression because regression predicts a numeric response.

- Some *classifiers* generate class membership probabilities (numeric) en route to predicting class membership (of the most likely class), so the distinction is not always clear-cut.
- There is essentially one regression algorithm (with many variants/enhancements/implementations) but there are *many* classification algorithms.
- You have seen 1 already (KNN) and we introduce another algorithm today.

Classification vs Regression

Supervised data models have a target.

If target is quantitative (continuous) then have a **regression model**, if categorical then **classification model**.

Classification models aim to:

- predict class/label for each new observation,
- define a decision boundary between classes,
- and possibly the probability of being in each class.

Regression models aim to

- predict a continuous value for each new observation.

Classification vs Regression

- Unlike regression, statistical distributions play a limited role in evaluating a classifier:
 - Scope for hypothesis testing is limited (there is no equivalent of the statsmodels diagnostic output (covered in topic 7)).
 - Rely on empirical metrics — accuracy, precision, recall, f1-score, auc, ...
- Classification metrics tend to be easier to use/understand than those in regression — classification metrics are based on counts of correct (or incorrect) cases divided by a subset of cases.
- Central concept in classification model is the **confusion matrix**:

		Predicted		
		Negative	Positive	
Actual	Negative	 True Negative (TN)	Type I error False Positive (FP)	N
	Positive	Type II error False Negative (FN)	 True Positive (TP)	P
		\hat{N}	\hat{P}	T

Unbalanced Classification Datasets

Practical classification datasets are often **unbalanced** — where the frequency of the classes in the target are very uneven:

- Telecommunication customer churn datasets.
- Credit Card Fraud Detection
- National Institutes of Health Chest X-Ray Dataset

Churn rate of 2%–10%.

0.172% (492 frauds / 284,807 transactions).

14 cases, (size 13 to 3,044) in 5,606 cases

Solutions

Use suitable metrics and/or

Summary of Classification Models

Model	Data Pre-processing*		Impact from		Summary
	Normalisation	Scaling	Collinearity	Outliers	
KNN	✓	✓	✓	✗	<ul style="list-style-type: none"> Local approximation, lazy learner Heavy computational requirements
Logistic Regression	✓	✗	✓	✓	<ul style="list-style-type: none"> Descriptive with good accuracy Reasonable computational requirements
Naïve Bayes	NA	NA	✓	✗	<ul style="list-style-type: none"> Works with categorical features only Suitable for small train datasets
Decision Tree	✗	✗	✓	✓	<ul style="list-style-type: none"> Easy to setup and interpret (XAI). Robust to missing data but not to noise. Slow training for larger sets.
Random Forest (Not this module)	✗	✗	✗	✗	<ul style="list-style-type: none"> High prediction accuracy Limited explainability Works with both continuous and categorical features
Support Vector Classifier (Not this module)	✗	✗	✗/✓	✓	<ul style="list-style-type: none"> High prediction accuracy Explainability depends on kernel Computational effort depends on kernel
Neural Networks (Not this module)	✗	✓	✓	✓	<ul style="list-style-type: none"> High prediction accuracy Self-extract features Heavy computational requirements

*Use StandardScaler, or RobustScaler if have outliers.

Lazy vs Eager Learners

Lazy learner

Stores training data (or only minor processing) and uses this to compute prediction when given test data.

- Does not generalise until after training
- Does not produce a standalone model
- Training data must be kept for prediction
- Local approximations
- Often based on *search*
- If new data is just added to the training data, it can respond more easily to changing conditions

Eager learner

Builds a model from the train set, before receiving new data for prediction

- Training has an extra goal: to generalise from the data
- Training has an extra output: standalone model
- Training data can be discarded after use
- Local and/or global approximations
- Based on *computation*
- Models *drift* with time, so not suited to highly dynamic contexts, as it needs retraining

Usually an (eager) model requires much less memory than a (lazy) training set.

A Non-perfect Test — Type I and Type II Errors

Consider an imperfect test with two outcomes, there are four possible outcomes:

Confusion Matrix

		Predicted		
		Negative	Positive	
Actual	Negative	✓ True Negative (TN)	Type I error False Positive (FP)	N
	Positive	Type II error False Negative (FN)	✓ True Positive (TP)	P
		\hat{N}	\hat{P}	T

- If the test is applied to $T = P + N = \hat{P} + \hat{N}$ observations / subjects / instances then we have four independent quantities TP , TN , FP , and FN .
- How do we combine these quantities into a single metric ?
- The fraction of correct results seems like a good idea

$$\text{accuracy} = \frac{TP + TN}{P + N}$$

But what happens, if we are testing for an rare event? Maximising accuracy will result in the test always returning negative.

- Ideally we want the probability of either error to be zero but that may not be possible.
- Depending on the conditions we often modify the test to reduce probability of the type of error we don't want at the expense of increasing the probability of the other — think court case vs medical condition.

Confusion matrix (Contingency table) Metrics

Accuracy — how well model is trained and performs in general

$$\text{Accuracy} = \frac{TP + TN}{P + N}$$

(How often is the classifier correct?)

- False negative rate (FNR) = $\frac{FN}{P} = 1 - TPR$
- Sensitivity = Recall** = True positive rate (TPR) = $\frac{TP}{P} = 1 - FNR$
(Of positive cases that exist how many did we mark positive?)
- Specificity** = $\frac{TN}{N} = 1 - FPR$
(When it's actually no, how often do we predict no?)
(Of cases that are negative, how many did we mark negative?)
- False positive rate (FPR) = false acceptance = $\frac{FP}{N} = 1 - \text{Specificity}$
- Precision** = positive predictive value (PPV) = $\frac{TP}{\hat{P}} = \frac{TP}{TP + FP}$
(Of cases that we marked positive, how many were correct?)

		Predicted		
		Negative	Positive	
Actual	Negative	✓ True Negative (TN)	Type I error False Positive (FP)	N
	Positive	Type II error False Negative (FN)	✓ True Positive (TP)	P
		\hat{N}	\hat{P}	T

Recall — important when the costs of false negatives are high

Precision — important when the costs of false positives are high

Confusion matrix (Contingency table) Metrics

F₁ Score

The F-measure or balanced F-score (F₁ score) is the harmonic mean of precision and recall:

$$F_1 = 2 \left[\frac{1}{\frac{1}{\text{precision}} + \frac{1}{\text{recall}}} \right] = 2 \left[\frac{\text{precision} \times \text{recall}}{\text{precision} + \text{recall}} \right]$$

A word of Caution ...

Consider the three binary classifiers A, B and C

	A		B		C	
	T	F	T	F	T	F
T	0.9	0.1	0.8	0	0.78	0
F	0	0	0.1	0.1	0.12	0.1

Metric	A	B	C	(best)
Accuracy	0.9	0.9	0.88	A,B
Precision	0.9	1.0	1.0	B,C
Recall	1.0	0.888	0.8667	A
F-score	0.947	0.941	0.9286	A

Clearly classifier A is useless since it always predicts label τ regardless of the input. Also, B is slightly better than C (lower off- diagonal total). Yet look at the performance metrics – *B is never the clear winner, and A has the best Accuracy, Recall and F₁-score, even though it just predicts the majority class! You can see why imbalanced data causes problems...*

We use some metrics because they are easy to understand, and not because they always give the “correct” result.

Mutual Information is a Better Metric

The mutual information between predicted and actual label (case) is defined

$$I(\hat{y}, y) = \sum_{\hat{y}=\{0,1\}} \sum_{y=\{0,1\}} p(\hat{y}, y) \log \frac{p(\hat{y}, y)}{p(\hat{y})p(y)}$$

where $p(\hat{y}, y)$ is the **joint probability distribution** function.

This gives the intuitively correct rankings $B > C > A$

Metric	A	B	C	(best)
Accuracy	0.9	0.9	0.88	A,B
Precision	0.9	1.0	1.0	B,C
Recall	1.0	0.888	0.8667	A
F-score	0.947	0.941	0.929	A
Mutual information	0	0.1865	0.1735	B

Cross Entropy Loss

➤ Cross-entropy loss (also known as log loss) is the classification equivalent of RMS Error

Definition 2 (Cross Entropy Loss)

If the classifier returns a *probability* estimate of the class membership, we can compute a metric from this directly, without calculating the confusion matrix first.

Let m be the number of cases in the training set, $\{y_i, i = 1, \dots, m\}$ be the *actual* target values of the training set, $\{\hat{y}_i, i = 1, \dots, m\}$ be the *predicted* target values of the training set, C be the number of possible class values, $\{c_k, k = 1, \dots, C\}$ be those class values, $\{w_{i,k} = 1 \text{ if } \hat{y}_i (\equiv \max_k p_{i,k}) = y_i \text{ and is } 0 \text{ otherwise, and } 0 \leq p_{i,k} \leq 1 \text{ be the probability predicted by the model that training case } i \text{ takes class value } c_k. \text{ Then}$

$$L_{CE}(X, y, f, a) = -\frac{1}{m} \sum_{i=1}^m \sum_{k=1}^C w_{i,k} \log(p_{i,k}) \geq 0 \quad (1)$$

The cross entropy loss is the scaled sum of the log probabilities assigned to incorrect predictions. Lower cross entropy loss indicates that the model assigns high probabilities to the correct class and low probabilities to incorrect classes. Therefore, it predicts correctly most of the time.

Binary Cross Entropy Loss

Definition 3 (Binary cross Entropy Loss)

In the special case of *binary* classification, $C \equiv 2$ and $p_{i,2} \equiv 1 - p_{i,1}$ (because $p_{i,1} + p_{i,2} = 1$), so we can drop the second subscript for p and just use p_i and $(1 - p_i)$. In this case

$$L_{CE}(\mathbf{X}, \mathbf{y}, f, \mathbf{a}) = -\frac{1}{m} \sum_{i=1}^m (w_{i,1} \log(p_i) + w_{i,2} \log(1 - p_i)) \geq 0 \quad (2)$$

➤ (Binary) cross entropy loss is often chosen as the loss function for deep learning classifiers. ➤

Focal Loss

See What is Focal Loss and when should you use it? for discussion and motivation

- Cross entropy loss can be over confident because $\log(p)$ falls so gently as p increases.
- This makes it more sensitive to outliers.
- It is also more likely to choose the majority class when the data is unbalanced.
- *Focal loss* was invented by the Computer Vision community to solve this problem.
- It weights the log term (with hyperparameters α and γ) so the weighted term falls more rapidly.

α is just a multiplier, and is implicitly $\alpha = 1$ above.

The focal loss (α and γ) hyperparameters can be tuned in the same way as model hyperparameters (say, k in KNN).

Micro Average vs Macro Average Performance

➤ In a multi-class classifier we have more than two classes.

To combine the metrics for individual classes to get an overall system metrics, we can apply either

Micro-Average Method weighted avg

From first principles: Sum up the individual true positives, false positives, and false negatives of the system for different classes and then calculate totals and ratios to get the statistics.

Macro-average Method macro avg

From existing metrics: Average the precision and recall of the system on different classes.

If the *support* for each class is the same, the micro-average and macro-average metrics will be the same, but will be different otherwise.

	precision	recall	f1-score	support
setosa	1.00	0.95	0.97	19
versicolor	0.81	0.74	0.77	23
virginica	0.71	0.83	0.77	18
accuracy			0.83	60
macro avg	0.84	0.84	0.84	60
weighted avg	0.84	0.83	0.84	60
